The equatorial plane of the new co-ordinate system must of necessity pass through the sun. It is a fortunate circumstance that, within the observational uncertainty, both the sun and Sagittarius A lie in the mean plane of the Galaxy as determined from the hydrogen observations. If the sun had not been so placed, points in the mean plane would not lie on the galactic equator. *[Blaauw et al. 1959]*

ABSTRACT

Recently, Goodman et al. argued that the very long, very thin infrared dark cloud “Nessie” lies directly in the Galactic midplane and runs along the Scutum–Centaurus Arm in position–position–velocity (p – p – v) space as traced by lower-density CO and higher-density NH₃ gas. Nessie was presented as the first “bone” of the Milky Way, an extraordinarily long, thin, high-contrast filament that can be used to map our Galaxy’s “skeleton.” Here we present evidence for additional bones in the Milky Way, arguing that Nessie is not a curiosity but one of several filaments that could potentially trace Galactic structure. Our 10 bone candidates are all long, filamentary, mid-infrared extinction features that lie parallel to, and no more than 20 pc from, the physical Galactic mid-plane. We use CO, N₂H⁺, HCO⁺, and NH₃ radial velocity data to establish the three-dimensional location of the candidates in p – p – v space. Of the 10 candidates, 6 also have a projected aspect ratio of $\geq 50:1$; run along, or extremely close to, the Scutum–Centaurus Arm in p – p – v space; and exhibit no abrupt shifts in velocity. The evidence presented here suggests that these candidates mark the locations of significant spiral features, with the bone called filament 5 (“BC_18.88-0.09”) being a close analog to Nessie in the northern sky. As molecular spectral-line and extinction maps cover more of the sky at increasing resolution and sensitivity, it should be possible to find more bones in future studies.

Key words: Galaxy: kinematics and dynamics – Galaxy: structure – ISM: clouds

6 OUT OF 10 WWT-IDENTIFIED BONE CANDIDATES TURN OUT TO BE EXCELLENT IN "3D" (POSITION-POSITION-VELOCITY SPACE)

PHYSICAL PROPERTIES OF LARGE-SCALE GALACTIC FILAMENTS

CATHERINE ZUCKER, CARA BATTERSBY, ALYSSA GOODMAN¹

¹Harvard-Smithsonian Center for Astrophysics

Abstract

The characterization of our Galaxy's longest filamentary gas features has been the subject of a number of studies in recent years, producing not only a sizeable sample of large-scale filaments, but also confusion as to whether all these features (e.g. "Bones", "Giant Molecular Filaments") are essentially the same. They are not. We undertake the first standardized analysis of the physical properties (densities, temperatures, morphologies, radial profiles) and kinematics of large-scale filaments in the literature. We expand and improve upon prior analyses by using the same data sets, techniques, and spiral arm models to disentangle the filaments' inherent properties from selection criteria and methodology. Our results suggest that the myriad filament finding techniques are uncovering different physical structures, with quantities length (10-268 pc), width (1-40 pc), mass ($3 \times 10^3 M_{\odot} - 1.1 \times 10^6 M_{\odot}$), aspect ratio (3:1 - 104:1), and dense gas fraction (0.2-100%) varying by at least an order of magnitude across the sample of 45 filaments. We perform a *position-position-velocity* (*p-p-v*) analysis on a subset of the filaments and find that while 60%-70% of the Galaxy, only 30-45% also exhibit kinematic proximity to purported spiral space defined by aspect ratio, temperature, and density, we broadly distinguish categories, which could be indicative of different formation mechanisms or historical "Bone-like" filaments show the most potential for tracing gross spiral structure; other categories could simply be large concentrations of molecular gas (GMCs,
